ABSTRACT

We ask whether galaxies in compact groups (CGs) remain special when they are compared with regular-group analogues rather than with the field alone. We use the CG₄ sample inherited from the Tricottet et al. construction after removing split systems, leaving 62 compact groups, and compare it with three regular-group controls: RG₄, Control_{4B}, and Control_{4C}. These controls respectively test true four-member regular groups, the luminous cores of richer regular groups, and projected compact cores around the brightest group galaxy. We combine Galaxy Zoo vote-fraction morphologies, SDSS stellar masses and specific star-formation rates, optical colours, emission-line and AGN-like diagnostics, and both adjusted and one-to-one matched control comparisons. CG₄ galaxies are more often classified as elliptical/smooth and less often as spiral/features than galaxies in the controls. This morphology signal survives adjustment for stellar mass, redshift, rank, and available group-scale quantities, and is also present in matched comparisons. The star-formation signal is weaker: CG₄ satellites have a lower raw star-forming fraction, especially relative to RG₄, but this contrast is not comparably robust after the adjusted and matched analyses. Among galaxies that remain star-forming, we find no robust compact-group offset from the star-forming main sequence. Colours, AGN-like fractions, magnitude gaps, and the limited H α diagnostics do not support a simple instantaneous-quenching, fossil-group, or AGN-driven explanation. A projected pairwise tidal-index diagnostic suggests that local tidal density accounts for part of the morphology signal. Compact groups therefore host a more morphologically evolved population, consistent with accumulated transformation in very dense group cores and/or preprocessing rather than a uniquely isolated compact-group quenching mode.

Key words. galaxies: groups: general – galaxies: evolution – galaxies: interactions – galaxies: star formation – galaxies: statistics

1. Introduction

Compact groups of galaxies are useful laboratories for environmental evolution because they combine high projected galaxy densities with relatively low velocity dispersions (Hickson 1982; Hickson et al. 1992). In such configurations, repeated tidal encounters, dynamical friction, mergers, gas stripping or consumption, and disk heating can plausibly accelerate the transformation of galaxies compared with more diffuse environments (Barnes 1985, 1989; Verdes-Montenegro et al. 2001). This expectation is closely connected to the broader morphology-density and star-formation-environment relation, in which galaxy structure and star-formation activity vary systematically with local density (Dressler 1980).

The interpretation of compact groups is nevertheless ambiguous. Projected selection can include chance alignments, and many Hickson-like systems need not be isolated bound entities. Simulations and redshift-space analyses have long shown that apparent compact groups may be transient alignments, dense substructures, or cores embedded in looser groups and richer haloes (Mamon 1986; Díaz-Giménez & Mamon 2010; Díaz-Giménez et al. 2012; Zheng & Shen 2021). The relevant observational question is therefore not only whether compact-group galaxies dif-

fer from field galaxies, but whether they remain different from galaxies occupying regular-group analogues selected with comparable luminosity, redshift, and membership constraints.

Recent structural work strengthens this motivation. Using S-PLUS imaging and single-Sérsic measurements, Montaguth et al. (2023, 2025, 2026b,a) identified transition galaxies and trends in the R_e -Sérsic-index plane that point to structural transformation in compact groups, with stronger signatures in non-isolated compact groups and host structures. These studies suggest that compact groups can mark sites of cumulative structural processing. They do not, however, by themselves answer whether compact-group galaxies remain distinct after comparison with regular-group cores selected from the same parent catalogues.

Our previous sample-construction paper (Tricottet et al. 2025) showed that many compact groups are not isolated systems, but appear as dense cores or substructures of richer environments. This result motivates the stricter comparison made here. We use the same compact-group and regular-group sample framework to ask whether CG galaxies are still special after controlling for stellar mass, redshift, galaxy rank, and available group-scale properties. We then ask which observable carries

the signal: star-formation class, Galaxy Zoo morphology, optical colour, AGN-like activity, fossil-like magnitude gaps, projected phase-space position, or local projected tidal density.

The paper is organized as follows. Section 2 describes the samples, the sSFR and morphology classifications, and the statistical hierarchy. Sections 3 and 4 present baseline population differences and group-scale diagnostics. Section 5 tests which signals survive adjusted and matched comparisons and examines secondary diagnostics. Section 6 relates the results to recent structural studies of compact-group galaxies, and Section 7 summarizes the conclusions.

2. Data and classifications

2.1. Samples

We use the compact-group and control samples constructed in our previous study [Tricottet et al. \(2025\)](#). We briefly recall their construction here. Galaxy properties are taken from the SDSS DR12 catalogue of [Tempel et al. \(2017\)](#), while regular groups are drawn from the SDSS DR7 group catalogue of [Lim et al. \(2017\)](#); the two catalogues were matched through SDSS object identifiers to define the Lim–Tempel working catalogue. Compact groups are selected from the modified Hickson compact-group catalogue of [Díaz-Giménez et al. \(2018\)](#). Starting from the reliable HMCs with exactly four members, we retain only systems in which all galaxies are present in the Lim–Tempel catalogue and impose the volume- and luminosity-complete limits $0.005 < z_{\text{BGG}} < 0.0452$ and $M_{r,\text{BGG}} \leq -21.81$, with all 4 galaxies lying within 3 magnitudes of the brightest group galaxy. This defines the parent CG₄ sample of 78 compact groups. The regular-group comparison samples are built from Lim–Tempel groups satisfying the same redshift and BGG-luminosity limits, with at least 4 members and at least 3 satellites within 3 magnitudes of the BGG. From this parent control catalogue, we define RG₄ groups as regular groups with exactly four members, excluding systems identical to a CG₄, and we additionally use the Control_{4B} and Control_{4C} samples, formed respectively from the 4 brightest galaxies and from the BGG plus its 3 closest projected companions in each parent regular group, after removing groups that share galaxies with CG₄s. In contrast to our previous study, we remove CGs classified as *split* following [Zheng & Shen \(2021\)](#). This reduces the compact-group sample from 78 to 62 groups. We also remove the systems associated with Lim group 3688 from our Control_{4B} and Control_{4C} samples. This group contains 6 galaxies with redshifts between 0.032 and 0.034, and 1 with a redshift of 0.048. This group appears to be spurious, and the outlying galaxy, although not the BGG, is selected in both our original Control_{4B} and Control_{4C} samples, significantly affecting the group velocity dispersion (1979 and 1981 km s^{−1}, respectively).

The three regular-group controls serve different physical purposes. RG₄ contains true regular groups with exactly four selected members and is the most direct four-member regular-group comparison. Control_{4B} contains the four brightest galaxies in richer regular groups and tests whether the CG₄ population resembles the luminous core of an ordinary group. Control_{4C} contains the BGG plus the three closest projected companions and is the most compact-core-like ordinary-group analogue. CG₄ is there-

fore tested against both equal-membership groups and regular-group cores, rather than against a single control definition.

We use SDSS DR 16 to retrieve stellar masses, star formation rates (SFRs), and Galaxy Zoo morphologies ([Lintott et al. 2011](#)). We specifically extract the columns `sfr_tot_p50`, `specsfr_tot_p50`, and `lgm_tot_p50` from the `galSpecExtra` table, and `p_el_debiased` and `p_cs_debiased` from the `zooSpec` table.

2.2. sSFR classification

To build a general star formation classification that could be uniformly applied to all our samples, we extracted galaxies from the SDSS DR 16 using the query shown in Listing 1.

Listing 1. Query used for selecting spectral & photometric data from the SDSS

We identify BPT-classifiable galaxies by requiring measured values of both emission-line ratios

$$\log_{10}([\text{N II}]\lambda 6584/\text{H}\alpha) \quad \text{and} \quad \log_{10}([\text{O III}]\lambda 5007/\text{H}\beta).$$

Among these galaxies, we flag broad AGN-like systems if they satisfy either

$$\log_{10} \frac{[\text{N II}]}{\text{H}\alpha} > 0,$$

Fig. 1. BPT diagram for galaxies with measured diagnostic line ratios. The AGN-like region is excluded from the sSFR calibration sample; galaxies without the required ratios are BPT-unclassified rather than classified as non-AGN by this diagram.

or if it lies above the empirical demarcation of Kauffmann et al. (2003):

$$\log_{10} \frac{[\text{O III}]}{\text{H}\beta} > \frac{0.61}{\log_{10}([\text{N II}]/\text{H}\alpha) - 0.05} + 1.3,$$

in which case they are excluded from the GMM calibration sample. Galaxies with missing diagnostic line ratios are BPT-unclassified, not proven non-AGN. They are retained for the broad sSFR status assignment when valid SDSS stellar mass and sSFR estimates are available, while the emission-line/AGN-like analysis below treats BPT-unclassified objects separately. The BPT-classifiable subset is shown in Fig. 1.

Galaxies with `specsfr_tot_p50` equal to -9999 in the SDSS are classified as quenched (for display purposes, they are assigned the arbitrary low value $10^{-14.0} \text{ Gyr}^{-1}$). The remaining galaxies are separated into star-forming and passive populations using a two-component Gaussian Mixture Model (GMM) in the $\log M_*$ – $\log \text{sSFR}$ plane. Its parameters are determined by minimizing the Kullback–Leibler divergence between the empirical and model densities (Kullback & Leibler (1951); McLachlan & Peel (2000)). For any trial parameter vector θ , we reconstruct the mixture means $\{\mu_i\}$, covariances $\{\Sigma_i\}$, and weights $\{w_i\}$ via a Cholesky-like decomposition and logistic mapping, optionally constraining the second component’s mean to isolate the passive population (Dempster et al. (1977)). The KL divergence is estimated by constructing a 2D histogram of the data and summing $p_{\text{data}} \ln(p_{\text{data}}/p_{\text{GMM}})$, with a small regularization ϵ to avoid singularities (Tojeiro et al. (2009); Bisigello et al. (2018)). We optimize θ via L-BFGS-B (with fallback to Nelder–Mead) over multiple guided and random initializations, selecting the solution with lowest divergence (Pedregosa et al. (2011); Bishop (2006)). Initial means are seeded by a median split in $\log \text{sSFR}$ to improve convergence and robustness against local minima (Rousseeuw (1987)). In the final fit, one component naturally aligns with the high-sSFR “star-forming sequence,” while the other captures the low-sSFR “passive” cloud, providing a data-driven division that agrees with previous multi-Gaussian decompositions of the $\text{SFR}-M_*$ plane (Wuyts et al. (2011); Hahn et al. (2019)). The decision boundaries, defined as the

Fig. 2. sSFR vs mass, star-forming/passive limit and Zoo morphologies for the SDSS control sample, excluding quenched galaxies.

loci where the posterior probabilities of adjacent components are equal, provide an objective criterion for delineating star-forming from passive galaxies. The GMM calibration excludes galaxies flagged as AGN-like where the required BPT ratios are available, while line-missing galaxies can still receive a broad sSFR class from their SDSS mass and sSFR measurements.

2.3. Raw sSFR fractions

The sSFR status for each sample is shown in Table 1. In the raw all-galaxy comparison, Fisher’s exact test gives star-forming-fraction p-values of $p = 6.5 \times 10^{-1}$ versus the `Control4B` sample, $p = 2.5 \times 10^{-1}$ versus `Control4C`, and $p = 1.8 \times 10^{-2}$ versus `RG4`. We treat these raw tests as descriptive because they do not adjust for stellar mass, rank, or group-scale differences.

The same comparison restricted to BGGs and satellites is also shown in Table 1. For BGGs, the p-values obtained with two-sided Fisher exact test are $p = 0.578$ against `Control4B`, $p = 0.587$ against `Control4C` and $p = 0.37$ against `RG4`. For satellites, the corresponding p-values are $p = 0.303$ against `Control4B`, $p = 0.033$ against `Control4C` and $p = 2.3 \times 10^{-4}$ against `RG4`. The satellite deficit is clearest in the raw comparison with `RG4` and is revisited below with adjusted and matched analyses.

2.4. Morphology classification

Morphologies are determined via the Galaxy Zoo citizen-science decision tree, in which each galaxy image receives multiple independent volunteer classifications that are aggregated into debiased vote fractions (Lintott et al. 2011). Those fractions are provided in the `zooSpec` table of the SDSS database through the `p_el_debiased` and `p_cs_debiased` columns. We classify a galaxy as “elliptical/smooth” if `p_el_debiased` is greater than 0.5, and as “spiral/features” if `p_cs_debiased` is greater than 0.5. All other cases are classified as “uncertain”. These are vote-fraction classes, not a full structural decomposition. In particular, the catalogue used here does not provide a clean E/S0 separation, so references below to elliptical or early-type galaxies should be read as Galaxy Zoo smooth/early-

Sample		Quenched	Passive	Starforming

type proxies rather than as a bulge-disc structural classification.

2.5. Statistical strategy

The analyses are organized hierarchically. Raw tables and exact tests provide descriptive baseline comparisons. Fisher or Barnard exact tests are used for two-sample categorical comparisons depending on the table structure, while rank-sum or bootstrap comparisons are used for distributional and median differences. Spearman and Pearson correlations are used only as diagnostics of monotonic or linear trends; when the coefficients are small, we interpret them as weak even if the p-values are formally small. Holm or Benjamini-Hochberg corrections are applied where multiple related tests are performed. The primary robustness layer consists of mass-, rank-, and environment-adjusted binomial models with group-clustered standard errors, followed by one-to-one matched control comparisons. Colours, AGN-like fractions, H α equivalent widths, magnitude gaps, crossing-time trends, projected phase space, and the pairwise tidal index are secondary diagnostics. The main conclusions below rely on signals that survive the adjusted and matched analyses, not on isolated exploratory tests.

3. Baseline population differences

3.1. Raw morphology fractions

The morphologies obtained for each sample are shown in Table 2. Barnard's two-sided exact tests were used to compare the fraction of each morphology between CG₄ and each control sample. The resulting p-values are $p = 1.4 \times 10^{-3}$ for ellipticals and $p = 1.2 \times 10^{-3}$ for spirals versus the Control_{4B} sample, $p = 3.3 \times 10^{-3}$ and $p = 3.4 \times 10^{-2}$ versus Control_{4C} and $p = 2.2 \times 10^{-7}$ and $p = 5.9 \times 10^{-7}$ versus RG₄. The galaxies in CG₄ systems, which we identified as cores of richer groups in Tricottet et al. (2025), show a robust raw excess of elliptical/smooth classifications and a deficit of spiral/features classifications. Figure 4 displays sSFR versus stellar mass for galaxies in the SDSS selection and in CG₄.

3.2. Morphology versus sSFR

Among star-forming CG₄ galaxies, 58 are classified as spiral (84.1% after removing galaxies with uncertain morphol-

Sample	Elliptical/smooth	Spiral/features	Uncertain
CG ₄	124 (50.0 %)	86 (34.7 %)	38 (15.3 %)
Control _{4B}	1106 (39.6 %)	1266 (45.3 %)	420 (15.0 %)
Control _{4C}	1215 (40.4 %)	1249 (41.6 %)	540 (18.0 %)
RG ₄	60 (26.8 %)	129 (57.6 %)	35 (15.6 %)
<i>SDSS selection</i>	<i>10091 (19.2 %)</i>	<i>34715 (66.1 %)</i>	<i>7725 (14.7 %)</i>

Table 2. Number of galaxies in each Galaxy Zoo vote-fraction morphology proxy for each sample.

ogy) and 11 are classified as elliptical (15.9% after removing galaxies with uncertain morphology). The corresponding numbers are 809 spiral galaxies (88.4%) and 106 elliptical galaxies (11.6%) for Control_{4B}, 851 spiral galaxies (84.3%) and 159 elliptical galaxies (15.7%) for Control_{4C}, and 91 spiral galaxies (91%) and 9 elliptical galaxies (9%) for RG₄. The probabilities that these fractions are drawn from the same distribution, estimated with Barnard two-sided exact test, are $p = 0.29$ against Control_{4B}, $p = 0.97$ against Control_{4C}, and $p = 0.19$ against RG₄. We therefore find neither a significant excess nor a deficit of star-forming elliptical galaxies in CG₄ relative to any control sample.

When restricting the comparison to BGGs, we find 36 elliptical BGGs (58.1% of the BGGs) and 17 spiral BGGs (27.4%) in CG₄. The corresponding numbers are 405 elliptical BGGs (58.0%) and 195 spiral BGGs (27.9%) in Control_{4B}, 424 elliptical BGGs (56.5%) and 216 spiral BGGs (28.8%) in Control_{4C}, and 21 elliptical BGGs (37.5%) and 26 spiral BGGs (46.4%) in RG₄. The p-values obtained with two-sided Fisher exact test are 1.00 against Control_{4B}, 0.88 against Control_{4C} and 0.03 against RG₄. Thus, BGG morphologies differ between CG₄ and RG₄: CG₄ BGGs have a higher elliptical fraction than RG₄ BGGs.

3.3. Population medians by sSFR class

3.4. Main sequence

We model the star-forming main sequence as a function of stellar mass using orders 1–4 (Fig. 8). We then use order 2 to compute the residual of each star-forming galaxy with respect to the main sequence, and show their distributions in Fig. 9.

The median main-sequence residual of CG₄ galaxies is:

- significantly different from that of Control_{4B}, with a median offset of $\Delta = 0.056$ ($0.029 \leq \Delta \leq 0.099$, bootstrap), corresponding to $p = 0.051$.
- significantly different from that of Control_{4C}, with a median offset of $\Delta = 0.082$ ($0.062 \leq \Delta \leq 0.122$, bootstrap), corresponding to $p = 0.010$.
- not significantly different from that of RG₄, with a median offset of $\Delta = 0.046$ ($-0.035 \leq \Delta \leq 0.099$, bootstrap), corresponding to $p = 0.535$.

A direct rank-sum comparison of the star-forming main-sequence offsets only identifies significant differences between CG₄ and

Control_{4C}, whose median offset is -0.060 with respect to the fitted sequence ($p = 0.03$).

Within CG₄, the star-forming main-sequence offsets of the Embedded, Isolated and Predominant classes remain statistically consistent with one another.

Fig. 5. Distributions of various quantities for galaxies according to their sSFR class.

4. Environmental and group-scale diagnostics

4.1. Distance to the BGG

We also compare the sSFR of satellite galaxies with their distance to the BGG, expressed both in projected kpc and in units of $\langle R_{ij} \rangle$.

Significant monotonic trends are detected in the following cases.

In CG₄, sSFR correlates with projected distance to the BGG with Spearman coefficient $\rho_s = 0.24$ for 177 satellites ($p = 1.2 \times 10^{-3}$) and Pearson coefficient $r = 0.21$ ($p = 4.1 \times 10^{-3}$).

In Control_{4B}, sSFR correlates with distance to the BGG normalized by $\langle R_{ij} \rangle$ with Spearman coefficient $\rho_s = 0.08$

Sample	$\log_{10}(\text{sSFR} [\text{yr}^{-1}])$		M_r		$\log(M_\star/M_\odot)$

for 1991 satellites ($p = 3.6 \times 10^{-4}$) and Pearson coefficient $r = 0.08$ ($p = 2.3 \times 10^{-4}$).

In Control_{4C}, sSFR correlates with projected distance to the BGG with Spearman coefficient $\rho_s = 0.25$ for 2143 satellites ($p < 10^{-6}$) and Pearson coefficient $r = 0.20$ ($p < 10^{-6}$).

In Control_{4C}, sSFR correlates with distance to the BGG normalized by $\langle R_{ij} \rangle$ with Spearman coefficient $\rho_s = 0.10$ for 2143 satellites ($p = 4.6 \times 10^{-6}$) and Pearson coefficient $r = 0.09$ ($p = 1.8 \times 10^{-5}$).

4.2. Dominance

We split groups into dominated systems, where the BGG contributes more than 60% of the group luminosity, and non-dominated systems. This split does not produce a strong compact-group signal by itself: CG₄ shows no significant dominated/non-dominated difference after the Benjamini–Hochberg false-discovery-rate (FDR) correction. Here p_{adj} denotes the FDR-adjusted p-value, and Cliff’s δ is a rank-based effect size ranging from -1 to 1.

Across the control and reference samples, the clearest binary separation is instead in group luminosity. Dominated systems have lower L_{group} than their non-dominated counterparts: Control_{4B} gives 9.1×10^{10} versus $1.28 \times 10^{11} L_\odot$ ($p_{\text{adj}} < 10^{-6}$, $\delta = -0.55$); Control_{4C} gives 8.49×10^{10} versus $9.54 \times 10^{10} L_\odot$ ($p_{\text{adj}} < 10^{-6}$, $\delta = -0.25$); and RG₄ gives 7.09×10^{10} versus $9.82 \times 10^{10} L_\odot$ ($p_{\text{adj}} = 7.8 \times 10^{-5}$, $\delta = -0.59$). The negative δ values mean that dominated groups tend to occupy the lower-luminosity side of each comparison.

The spiral-fraction correlations show a broader environmental pattern rather than a clean dominated/non-dominated dichotomy. The most coherent set appears in Control_{4C}, where S_{frac} increases with $\langle R_{ij} \rangle$ in both dominated and non-dominated groups ($\rho_s = 0.38$, $p < 10^{-6}$ and $\rho_s = 0.35$, $p < 10^{-6}$), while weaker negative trends are found with σ_v and L_{group} . Control_{4B} contributes only weaker non-dominated-group correlations. In CG₄, the significant trends occur in small subsets, with S_{frac} decreasing with L_{group} among dominated groups ($\rho_s = -0.50$, 36 groups) and with $\Delta V_{\text{BGG}}/\sigma_v$ among non-dominated groups ($\rho_s = -0.53$, 26 groups); we therefore treat these as supporting diagnostics rather than the main dominance result. The full distributional and correlation diagnostics are shown in Figs. 12 and 13.

4.3. Morphology and domination

When we further split the samples by domination and by the morphology of the BGG, significant effects only appear in

Control_{4B} dominated groups, where the median satellite spiral fraction is 1.00 for spiral BGGs and 0.67 for elliptical BGGs. The corresponding group-level odds ratio is 1.84 ($p = 0.01$), while the satellite-level clustered fit gives an odds ratio of 1.84 ($p = 0.02$);

Control_{4C} dominated groups, where the median satellite spiral fraction is 0.67 for spiral BGGs and 0.50 for elliptical BGGs. The corresponding group-level odds ratio is 1.84

Fig. 6. Distributions of various quantities for galaxies according to the BGG sSFR class (BGG included).

Fig. 7. Distributions of various quantities for satellites according to the BGG sSFR class.

($p = 2.1 \times 10^{-5}$), while the satellite-level clustered fit gives an odds ratio of 1.84 ($p = 2.7 \times 10^{-5}$).

4.4. Crossing time

The crossing-time diagnostic mainly separates systems by dynamical scale rather than by luminosity alone. Shorter t_{cross} systems have larger virial mass-to-light ratios and virial masses: the correlations with $\log(M_{\text{VT}}/L_r)$ and $\log(M_{\text{VT}})$ are $\rho_S = -0.39$ ($p < 10^{-6}$) and $\rho_S = -0.33$ ($p < 10^{-6}$), respectively, over 816 groups. By contrast, the relation with total group luminosity is formally significant but very weak ($\rho_S = 0.08$, $p = 0.03$). We therefore read t_{cross} as a dynamical compactness indicator tied primarily to virial mass and mass-to-light ratio, with little independent leverage from L_{group} . Figures 14–16 show the corresponding projected and three-dimensional trends.

4.5. Optical colours

We derive the $(u - r)$, $(u - g)$, $(g - r)$ and $(r - i)$ colours from the matched SDSS photometry. The retained matches include 110 of 248 galaxies in CG4, 931 of 2792 galaxies in Control4B, 1478 of 3004 galaxies in Control4C, 102 of 224 galaxies in RG4. Stellar mass is a confounding vari-

Fig. 8. Polynomial fits of orders 1–4 to the star-forming main sequence.

able in colour comparisons (Alpaslan et al. 2015); we therefore model each colour jointly with $\log(M_*/M_\odot)$ rather than comparing unadjusted colour distributions.

Fig. 9. Main-sequence residual distributions for the star-forming galaxies in each sample.

Fig. 10. sSFR as a function of projected distance to the BGG, in kpc, for satellite galaxies in each sample.

4.5.1. Catalogue colour–mass relations

The hypothesis of a common colour–mass slope across catalogues is rejected for u-r ($p = 4.96 \times 10^{-4}$), u-g ($p = 0.00203$), g-r ($p = 1.46 \times 10^{-4}$), r-i ($p = 0.00495$). After Holm correction for the directional comparisons, significantly steeper CG₄ slopes are found for u-r relative to Control_{4C}, with $\Delta b = 0.289$ ($p_{\text{Holm}} = 0.00163$); for u-r relative to SDSS, with $\Delta b = 0.232$ ($p_{\text{Holm}} = 0.00163$); for u-g relative to Control_{4C}, with $\Delta b = 0.237$ ($p_{\text{Holm}} = 0.00287$); for u-g relative to SDSS, with $\Delta b = 0.186$ ($p_{\text{Holm}} = 0.00165$). These relations are shown in Fig. 17.

4.5.2. Satellite colours

To isolate an environmental difference, we pool satellites from the control catalogues as the ordinary-group population and compare them with CG₄ satellites at the common

Fig. 11. sSFR as a function of projected distance to the BGG normalized by $\langle R_{ij} \rangle$ for satellite galaxies in each sample.

Fig. 12. Distributions of the main group-scale observables in dominated and non-dominated systems.

reference mass $\log(M_{\star}/M_{\odot}) = 9.885$. At this mass, compact-group satellites are 0.124 mag bluer in u-r ($p_{\text{Holm}} = 0.00909$) and 0.106 mag bluer in u-g ($p_{\text{Holm}} = 0.00737$). The compact and ordinary colour–mass slopes also differ in u-r ($b_{\text{compact}} = 0.819$, $b_{\text{ordinary}} = 0.344$, $p_{\text{Holm}} = 2.21 \times 10^{-5}$), u-g ($b_{\text{compact}} = 0.532$, $b_{\text{ordinary}} = 0.150$, $p_{\text{Holm}} = 1.42 \times 10^{-4}$), g-r ($b_{\text{compact}} = 0.287$, $b_{\text{ordinary}} = 0.195$, $p_{\text{Holm}} = 2.9 \times 10^{-4}$). Figure 18 displays the corresponding fitted relations.

4.5.3. Robustness of the satellite colour result

The SDSS-photometry subset is not representative of the full galaxy catalogues: matched galaxies are systematically less massive, more actively star-forming and more fre-

Fig. 13. Bootstrap distributions of the Spearman coefficients for the group-property pairs selected by the XOR domination criterion.

Fig. 14. Crossing time versus virial mass-to-light ratio for the compact groups and their controls.

quently satellites than unmatched galaxies. The fractions with all four colours are 44.4% in CG4, 33.3% in Control4B, 49.2% in Control4C, 45.5% in RG4.

We therefore refit the satellite colours with cluster-robust standard errors, using catalogue-qualified group identifiers. In the pooled comparison adjusted only for stellar mass and redshift, none of the four CG4 coefficients is significantly negative after Holm correction. After additionally controlling for morphology and sSFR class, negative coefficients appear in $(u-r)$ ($\Delta = -0.127$ mag, $p_{\text{Holm}} = 0.0177$), $(u-g)$ ($\Delta = -0.101$ mag, $p_{\text{Holm}} = 0.0271$). These adjusted coefficients are control-sample dependent: the significant individual comparisons are Control4C in $(u-r)$, Control4C in $(u-g)$, Control4C in $(g-r)$.

Within sSFR classes, no negative CG4 residual difference survives correction for the four colours. Likewise, no within-morphology residual difference survives the same

Fig. 15. Crossing time versus virial mass for the compact groups and their controls.

Fig. 16. Three-dimensional view of the crossing time, virial mass and group luminosity space.

correction. Thus, the data do not localize the colour effect to the star-forming spiral population expected for a simple interaction-triggered star-formation scenario.

Figure 19 summarizes the model and control-sample dependence. Taken together, these tests do not establish a robust global blue offset for CG4 satellites; the negative full-model coefficients should instead be treated as a control-sensitive exploratory result.

4.5.4. Radial and group-level colour trends

The residual colours become bluer at larger projected distance from the BGG in CG4. After Holm correction within each distance metric, significant CG4 correlations are found for $(u-r)$ ($\rho_s = -0.379$, $p_{\text{Holm}} = 2.6 \times 10^{-4}$), for $(u-g)$ ($\rho_s = -0.336$, $p_{\text{Holm}} = 0.0011$), for $(g-r)$ ($\rho_s = -0.257$,

Fig. 17. Optical colour as a function of stellar mass for CG₄, the three control catalogues and the matched SDSS reference sample. Dashed lines show the fitted catalogue relations.

$p_{\text{Holm}} = 0.00922$). This radial trend is consistent with stronger processing near the group centre and a less processed outer population, rather than centrally triggered blue colours.

At the group level, crossing time correlates with mean satellite $\Delta(u-r)$ ($\rho_S = -0.418$, $p_{\text{Holm}} = 0.013$), median satellite $\Delta(u-r)$ ($\rho_S = -0.409$, $p_{\text{Holm}} = 0.0167$), satellite blue fraction ($\rho_S = 0.369$, $p_{\text{Holm}} = 0.0393$). These group-level relations remain exploratory because many groups contribute only a small number of colour-matched satellites.

4.5.5. BGG and satellite colours

The mean satellite colour varies with the BGG colour across the combined group sample: for u-r, $r_P = 0.360$

($p_{\text{Holm}} = 7.91 \times 10^{-7}$) and $\rho_S = 0.321$ ($p_{\text{Holm}} = 1.3 \times 10^{-5}$); for u-g, $r_P = 0.326$ ($p_{\text{Holm}} = 6.01 \times 10^{-6}$) and $\rho_S = 0.325$ ($p_{\text{Holm}} = 1.3 \times 10^{-5}$); for g-r, $r_P = 0.340$ ($p_{\text{Holm}} = 2.94 \times 10^{-6}$) and $\rho_S = 0.283$ ($p_{\text{Holm}} = 1.13 \times 10^{-4}$); for r-i, $r_P = 0.142$ ($p_{\text{Holm}} = 0.0464$) and $\rho_S = 0.232$ ($p_{\text{Holm}} = 0.00103$). After Holm correction, the BGG–satellite colour slope in CG₄ does not differ significantly from any control catalogue in any of the four colours. Figure 21 shows these group-level relations.

Taken together, these results suggest a limited degree of BGG–satellite concordance. The direct evidence is clearest for colour: redder BGGs are associated with redder mean satellite populations. A similar tendency appears in the satellite-only split by BGG sSFR class in Table 5, where satellites around passive BGGs have lower median sSFR than those around star-forming BGGs. The morphology

Fig. 18. Satellite colour–mass relations in compact and ordinary groups. The fitted lines show both colour offsets at the reference mass and differences in slope.

signal is more restricted, appearing only in dominated control systems. We therefore treat concordance as a secondary pattern in the present analysis rather than as a separate population-level classification.

($p_{\text{Holm}} = 1$); g-r: $\Delta = 0.007$ mag ($p_{\text{Holm}} = 1$); r-i: $\Delta = 0.001$ mag ($p_{\text{Holm}} = 1$). Thus, no dominated/non-dominated BGG colour offset remains significant after controlling for stellar mass. The mass dependence and class fits are shown in Fig. 22.

4.5.6. BGG colours and luminosity domination

The BGG stellar-mass distributions are significantly different between the domination classes ($p = 7.32 \times 10^{-4}$); the median $\log(M_*/M_\odot)$ values are 11.092 for dominated and 10.976 for non-dominated BGGs. Before mass adjustment, a significant colour difference is found in g-r ($\Delta_{\text{median}} = 0.021$, $p_{\text{Holm}} = 0.00157$). At the common reference mass $\log(M_*/M_\odot) = 11.042$, the adjusted results are u-r: $\Delta = -0.002$ mag ($p_{\text{Holm}} = 1$); u-g: $\Delta = -0.010$ mag

5. Robustness: what drives the compact-group differences?

The previous sections establish that CG₄ galaxies differ from the control catalogues in their population mix, especially in morphology and in the star-forming fraction of satellites. We now ask whether these differences survive after controlling for stellar mass, rank and available group-scale quantities, and whether they are better interpreted

Fig. 19. Robustness of the satellite colour coefficients. Left: pooled ordinary-group comparison before and after controlling for morphology and sSFR class. Right: mass- and redshift-adjusted comparisons against each control catalogue separately. Points show the CG₄ minus ordinary coefficient and bars show 95% confidence intervals; negative values indicate bluer CG₄ satellites.

Fig. 20. Mass- and redshift-adjusted satellite $(u-r)$ and $(u-g)$ residuals as a function of projected distance to the BGG. Lines connect binned medians for CG₄ and the pooled ordinary-group satellites; extreme plotting tails are omitted for readability, while the reported rank correlations use the full matched sample. More negative residuals are bluer than the ordinary-satellite reference relation.

as compact-group-specific evolution, preprocessing in dense halo cores, or catalogue-selection effects.

5.1. Mass-, rank- and environment-adjusted galaxy properties

We fit binomial models to the combined galaxy catalogues, standardizing the continuous predictors and using group-clustered standard errors. The common adjustment set in-

Fig. 21. Mean satellite colour versus BGG colour for groups with matched photometry. The dotted line is the one-to-one relation and dashed lines are catalogue-specific fits.

cludes stellar mass, redshift, satellite/BGG rank, group luminosity and velocity dispersion when sufficiently complete.

For passive status, the CG_4 odds ratio is 1.20, with 95% confidence interval [0.88, 1.63] and $p_{\text{Holm}} = 0.485$.

For passive satellite status, the CG_4 odds ratio is 1.31, with 95% confidence interval [0.95, 1.80] and $p_{\text{Holm}} = 0.390$.

For star-forming satellite status, the CG_4 odds ratio is 0.76, with 95% confidence interval [0.56, 1.05] and $p_{\text{Holm}} = 0.390$.

For elliptical morphology, the CG_4 odds ratio is 1.62, with 95% confidence interval [1.21, 2.16] and $p_{\text{Holm}} = 0.007$.

For elliptical BGG morphology, the CG_4 odds ratio is 0.90, with 95% confidence interval [0.46, 1.74] and $p_{\text{Holm}} = 0.751$.

For spiral morphology, the CG_4 odds ratio is 0.62, with 95% confidence interval [0.46, 0.83] and $p_{\text{Holm}} = 0.007$.

Compact-group membership therefore remains independently associated with morphology after the available adjustments: CG_4 galaxies have a higher probability of being elliptical and a lower probability of being spiral. In contrast, the adjusted passive and star-forming satellite coefficients are weaker and do not provide evidence for an instantaneous star-formation difference that remains significant after correction.

5.2. Matched-control comparison

We matched 234 CG_4 galaxies one-to-one to 234 ordinary-group galaxies without replacement, requiring common propensity-score support, a 0.2-standard-deviation caliper and exact rank strata. The propensity model uses logMstar,

Fig. 22. BGG colour–mass relations split by luminosity domination. Comparing the fitted relations at a common stellar mass separates colour effects from the different mass distributions.

z numeric, rank, log group luminosity, velocity dispersion. Projected distance is retained as a phase-space and interaction diagnostic rather than matched away because it partly defines compactness and has limited overlap. The largest absolute standardized mean difference changed from 0.28 before matching to 0.14 afterwards.

The matched CG₄-minus-control difference in passive fraction is 0.098, with 95% bootstrap interval [0.017, 0.175] and $p_{\text{Holm}} = 0.054$.

This is suggestive but not formally significant after correction, so we treat the passive-fraction excess as borderline.

The corresponding CG₄-minus-control difference in star-forming fraction is -0.098 , with 95% bootstrap interval $[-0.175, -0.017]$ and $p_{\text{Holm}} = 0.054$.

The matched CG₄-minus-control difference in elliptical fraction is 0.197, with 95% bootstrap interval [0.090, 0.303] and $p_{\text{Holm}} < 10^{-6}$.

The matched CG₄-minus-control difference in spiral fraction is -0.197 , with 95% bootstrap interval $[-0.303, -0.090]$ and $p_{\text{Holm}} < 10^{-6}$.

Among matched star-forming galaxies, the residual-sSFR difference is -0.096 , with 95% bootstrap interval $[-0.221, 0.015]$ and $p = 0.084$.

The main interpretation does not rely on the exact GMM division of the sSFR plane. Repeating the key satellite comparison with a fixed threshold, $\log_{10}(\text{sSFR}/\text{yr}^{-1}) = -11.0$, gives CG₄ and RG₄ satellite star-forming fractions of 40.7% and 60.2%, respectively, a CG₄-RG₄ difference of -19.6 percentage points ($p = 3.6 \times 10^{-4}$). The qualitative hierarchy is unchanged: the morphology result is independent

Fig. 23. Adjusted CG₄ odds ratios. Bars show 95% confidence intervals; the vertical line marks equal odds.

Fig. 24. CG₄-minus-control effects after one-to-one matching. Bars show 95% bootstrap confidence intervals.

Fig. 25. Absolute standardized mean differences before and after matching.

of the sSFR threshold, whereas the passive/star-forming contrast remains more sensitive to modelling choices.

The matched comparison is therefore consistent with the adjusted models: the most robust compact-group signal is morphological, while the passive and star-forming-fraction signals are more model-dependent.

5.3. Satellite segregation around the brightest group galaxy

The previous sections show global differences between CG₄ and RG₄ satellites. We now ask whether these differences

Fig. 26. Passive satellite fraction as a function of projected-distance rank from the BGG. Points show CG₄ and RG₄ fractions; bars show group-cluster bootstrap 16th–84th percentile intervals.

are concentrated near the BGG, as expected for accelerated evolution in the dense inner group, or whether they persist across the satellite population. The analysis uses 177 CG₄ and 166 RG₄ satellites, excludes rank-1 galaxies, ranks satellites by projected BGG-centric distance, and measures passive and early-type fractions with group-cluster bootstrap uncertainties. When available, we also use $|\Delta v_{\text{BGG}}|/\sigma_v$, with $\Delta v_{\text{BGG}} = c(z_{\text{gal}} - z_{\text{BGG}})/(1 + z_{\text{group}})$, as a projected phase-space diagnostic. Similar projected phase-space coordinates are often used as observational proxies for satellite infall state or quenching time, but only statistically (Mahajan et al. 2011; Oman & Hudson 2016; Wetzel et al. 2013).

In the innermost satellite-distance bin, the passive fractions are 68.9% for CG₄ and 48.2% for RG₄, a CG₄–RG₄ difference of 20.6 percentage points. The corresponding early-type fractions are 65.4% and 35.6%, with a difference of 29.8 percentage points.

The passive-fraction contrast is similar between the inner and outer distance ranks, so the data do not isolate the CG₄ offset to the immediate BGG environment.

After adjusting for stellar mass, redshift, distance bin, and available group-scale controls, the passive-status model gives a CG₄ odds ratio of 1.27 (95% CI 0.47–3.46; $p = 0.640$).

The analogous early-type model gives a CG₄ odds ratio of 2.57 ($p = 0.058$).

A nearest-neighbour mass–redshift matched check uses 128 CG₄–RG₄ satellite pairs. The matched passive-fraction difference is 9.4 percentage points, and the matched early-type difference is 19.6 percentage points.

Projected phase-space coordinates should not be read as orbital reconstructions for individual galaxies. In compact groups the member counts are small, velocity dispersions are noisy, and projection mixes recently accreted and long-resident satellites. We therefore treat these bins as an observational diagnostic of where the CG₄–RG₄ population contrast appears, rather than as a direct dynamical clock.

Fig. 27. Early-type satellite fraction as a function of projected-distance rank from the BGG. Because the catalogue separates ellipticals, spirals, and uncertain morphologies but not S0 galaxies, early type is equivalent to elliptical in this diagnostic.

Fig. 28. Passive satellite fraction in coarse projected phase-space bins. Inner and outer refer to projected-distance rank from the BGG; low and high velocity are split at $|\Delta v_{\text{BGG}}|/\sigma_v = 1$.

5.4. Magnitude gaps and fossil-like assembly

We define $\Delta m_{12} = M_{r,2} - M_{r,1}$ and $\Delta m_{14} = M_{r,4} - M_{r,1}$, so that a more dominant BGG has a positive, larger gap.

For Δm_{12} , the CG₄ and control medians are 1.17 and 1.09 mag, respectively ($p_{\text{Holm}} = 0.705$).

For Δm_{14} , the CG₄ and control medians are 2.56 and 2.59 mag, respectively ($p_{\text{Holm}} = 0.705$).

The compact-group morphology signal is therefore not accompanied by a significant excess in these simple fossil-like magnitude-gap indicators.

The correlation between Δm_{12} and passive satellite fraction is $\rho_s = -0.15$ ($p_{\text{Holm}} < 10^{-6}$).

5.5. Recently quenched candidates

The catalogues do not contain both D_n4000 and $H\delta_A$, so a post-starburst classification is not possible. We therefore perform only a limited $H\alpha$ -equivalent-width comparison, using the SDSS convention in which negative equivalent width denotes emission. We classify strong $H\alpha$ emission using $\text{h_alpha_eqw} \leq -3$ Angstrom.

The strong-emission fraction is 32.3% in CG₄, 41.0% in Control4B, 45.7% in Control4C, 56.9% in RG₄.

Fig. 29. Distributions of the first-second and first-fourth magnitude gaps in CG₄ and the pooled controls.

Fig. 30. Passive satellite fraction as a function of the first-second magnitude gap.

Fig. 31. $H\alpha$ equivalent-width distributions used for the limited recent-quenching diagnostic.

Relative to Control4B, the CG₄ strong-emission fraction differs by -0.087 ($p_{\text{Holm}} = 0.012$).

Relative to Control4C, the CG₄ strong-emission fraction differs by -0.135 ($p_{\text{Holm}} = 2.4 \times 10^{-4}$).

Relative to RG₄, the CG₄ strong-emission fraction differs by -0.246 ($p_{\text{Holm}} = 1.5 \times 10^{-6}$).

These limited $H\alpha$ results indicate that CG₄ galaxies have a lower strong-emission fraction than in each control sample in the current catalogue, but they do not provide a direct post-starburst or recently-quenched classification.

Fig. 32. AGN-like fractions among galaxies with BPT-classifiable emission-line ratios. BPT-unclassified galaxies are not counted as non-AGN in this diagnostic.

5.6. Emission-line and AGN-like populations

The complementary emission-line analysis classifies BPT-star-forming, composite and broad AGN-like populations for galaxies with the required diagnostic line ratios. BPT-unclassified galaxies are excluded from the AGN-like fraction denominator rather than treated as confirmed non-AGN. Among BPT-classified CG₄ galaxies, the AGN-like fraction is 38.0%.

After mass and environment adjustment, the CG₄ AGN-like odds ratio is 1.14 ($p = 0.451$).

Thus, AGN-like activity does not provide a robust independent compact-group discriminator in this analysis.

5.7. Pairwise tidal index

The pairwise analysis reconstructs projected separations and velocity differences for 6268 galaxies and tests whether adding $\sum_j M_{*,j}/R_{ij}^3$ changes the adjusted CG₄ coefficient.

For passive status, the baseline CG₄ odds ratio is 1.20 ($p = 0.227$), while the model including the tidal index gives a CG₄ odds ratio of 0.80 ($p = 0.170$). The tidal-index term itself has odds ratio 1.65 ($p < 10^{-6}$).

For elliptical morphology, the baseline CG₄ odds ratio is 1.65 ($p = 4.1 \times 10^{-4}$), whereas the model including the tidal index gives a CG₄ odds ratio of 1.15 ($p = 0.346$). The tidal-index term has odds ratio 1.56 ($p < 10^{-6}$). This suggests that the reconstructed local tidal-density proxy absorbs much of the unadjusted CG₄ morphology coefficient, although the result remains an exploratory projected-pair diagnostic.

5.8. Selection diagnostics

The fractions with complete measurements for the major derived quantities are shown in Fig. 34. The colour-matched versus unmatched comparisons quantify shifts in stellar mass, redshift, rank, star-formation class and morphology.

The median nearest-neighbour angular separation is 100.9 arcsec in CG₄ and 209.0 arcsec in the controls; the fractions below the 55-arcsec SDSS fibre-collision scale are 19.4% and 9.3%, respectively.

Fig. 33. Passive status as a function of the reconstructed pairwise tidal index. Colours distinguish CG₄ from control galaxies.

No major availability difference meets both criteria of corrected significance and a difference exceeding 10 percentage points.

The group-scale availability row is based on the group covariates available for this catalogue: radius scale, velocity dispersion, group luminosity, and BGG luminosity dominance. A harmonized group-mass estimate is not available in these tables, so models that request it omit that covariate.

6. Relation to recent structural studies of compact-group galaxies

A complementary interpretation of the present results is provided by the recent series of studies by Montaguth et al. (2023, 2025, 2026b,a). Using multiwavelength S-PLUS imaging and single-Sérsic structural fits, these authors identified a population of “transition” galaxies, broadly corresponding to red systems with relatively low or intermediate Sérsic index, whose location in the R_e – n plane suggests ongoing structural transformation in compact groups. In particular, Montaguth et al. (2023) found that compact-group transition galaxies include a population that is smaller and more centrally concentrated than analogous field galaxies, while Montaguth et al. (2025) showed that this signature is stronger in non-isolated compact groups embedded in larger structures. Montaguth et al. (2026b) further compared non-isolated compact groups with their surrounding host-group galaxies and found that the compact-group members display higher quenched fractions, a larger early-type fraction, and distinct transition-galaxy (R_e – n) distributions. Finally, Montaguth et al. (2026a) showed that the environmental dependence of the stellar mass–size relation is weak for early- and late-type galaxies, but strongest for transition galaxies, whose mass–size slopes and Sérsic-index distributions become more early-type-like in groups and compact groups.

Our analysis addresses a related but stricter question. Rather than comparing compact groups primarily with the field, or non-isolated compact groups with their immediate host structures, we ask whether compact-group galaxies remain different from galaxies in regular four-member group analogues after controlling for stellar mass, redshift, rank,

Fig. 34. Availability fractions for the major derived quantities in each sample.

Diagnostic	Baseline CG ₄ signal	Survives adjusted/ matched analysis?	Interpretation
Elliptical/smooth fraction	Enhanced in CG ₄	Yes	Robust accumulated morphology signal.
Spiral/features fraction	Reduced in CG ₄	Yes	Reduced late-type vote-fraction population.
Satellite star-forming fraction	Reduced, especially versus RG ₄	Weak or borderline	Partly explained by mass, rank, environment, or preprocessing.
Star-forming main-sequence residual	Weak and control-dependent	No robust offset	No strong instantaneous SFR enhancement or suppression among remaining star-forming galaxies.
Satellite colours	Colour-slope and residual hints	Control-sensitive	Exploratory; not a simple uniform reddening or blueing of CG ₄ satellites.
AGN-like fraction	No robust independent signal	No	Not an AGN-driven explanation.
Magnitude gaps	No significant excess	No	Not fossil-like under the simple gap diagnostics used here.
Pairwise tidal index	Local projected density proxy is informative	Absorbs much of the morphology coefficient	Local tidal density likely contributes to the morphology signal.

Table 6. Result hierarchy. Baseline tests describe where CG₄ differs from the controls; the main interpretation is based on diagnostics that remain after adjusted or matched comparisons.

and available group-scale quantities. In this framework, the most robust residual signal is morphological: compact-group membership remains associated with an enhanced probability of being classified as elliptical and a reduced probability of being classified as spiral. By contrast, the passive and star-forming satellite fractions are more sensitive to the adopted control sample and to the adjustment or matching procedure.

The two sets of results are therefore not contradictory. The structural work of [Montaguth et al. \(2023, 2025,](#)

[2026b,a](#)) identifies the likely nature of the transformation: disk fading, increasing central concentration, and/or bulge growth in galaxies occupying an intermediate region between blue late-type disks and red early-type systems. Our results indicate that, when compact groups are compared with regular-group analogues rather than with the field alone, the clearest surviving signature is the accumulated morphological state of the galaxy population, whereas an instantaneous star-formation offset is less robust. This suggests that compact groups should not be interpreted simply

Fig. 35. Stellar-mass distributions of galaxies with and without complete matched colour measurements.

as environments with ongoing enhanced quenching at the present epoch. They are more plausibly very dense regions in which past interactions, local tidal density, and preprocessing in larger haloes have already shifted part of the galaxy population toward earlier morphologies.

A useful way to reconcile these views is to regard the compact-group signal as primarily structural and cumulative. In that picture, the compact configuration may accelerate morphological transformation, but some of the observed differences may also reflect the fact that many compact groups are the dense cores or substructures of larger systems. Future work combining the structural diagnostics of S-PLUS-like analyses, especially R_e , Sérsic index, transition-galaxy classifications, and mass-size residuals, with the matched regular-group control framework used here would provide a direct test of whether the compact-group transformation is unique to compact configurations or is the high-density limit of more general group preprocessing.

7. Conclusion

We have tested whether galaxies in CG₄ compact groups remain special after removing split systems and comparing them with three regular-group analogues: RG₄, Control_{4B}, and Control_{4C}. The comparison was designed to separate compact configurations from ordinary four-member groups, luminous group cores, and projected compact cores around BGGs.

The main result is morphological. CG₄ galaxies have an enhanced elliptical/smooth Galaxy Zoo fraction and a reduced spiral/features fraction. This signal survives the mass-, redshift-, rank-, and group-adjusted binomial models and is also recovered in the one-to-one matched-control analysis.

The star-formation result is weaker. CG₄ satellites have a lower raw star-forming fraction, especially relative to RG₄, but the adjusted and matched evidence is weaker or borderline. Among galaxies that remain star-forming, CG₄ galaxies do not show a robust offset from the fitted star-forming main sequence.

The secondary diagnostics do not identify a simple alternative driver. The colour results are control-sensitive and based on a biased colour-matched subset. AGN-like frac-

tions and magnitude gaps do not explain the morphology signal, the H α diagnostic is limited by missing age-sensitive spectral indices, and projected phase-space trends do not localize the passive difference uniquely to the nearest satellites.

We therefore interpret CG₄ galaxies as a more morphologically evolved population, consistent with accumulated transformation in very dense environments, dense group cores, and/or preprocessing. The pairwise tidal-index experiment suggests that local projected tidal density accounts for part of the compact-group morphology coefficient, so the result should not be read as evidence for a uniquely isolated compact-group quenching mechanism.

Future work should connect this regular-group control framework directly to structural measurements, including R_e , Sérsic index, transition-galaxy classifications, mass-size residuals, and better spectroscopic post-starburst diagnostics. Those measurements would test whether the morphology signal isolated here is the same cumulative structural transformation highlighted by recent S-PLUS studies.
